Abstract—We consider an ultra-reliable low-latency communication (URLLC) system with short packets employing hybrid automatic repeat request (HARQ). Depending on the delay of HARQ feedback and retransmissions, the latency constraint can be either violated or fulfilled at the expense of power consumption. We focus on the energy-latency tradeoff and examine whether it is better to do one-shot transmission or use HARQ. We analyze the energy consumption for incremental redundancy (IR) HARQ and compare it with the no HARQ case. The analysis relies on closed-form expressions for the outage probability of IR-HARQ with variables both the blocklength and the power. Our results show that for a wide range of blocklength, when the feedback delay is more than half the latency constraint, it is beneficial in terms of energy to use one-shot transmission (i.e. no HARQ).

I. INTRODUCTION

Future evolution of mobile communication systems (5G new radio) is giving rise to new uses of wireless communications in areas such as augmented and virtual reality (AR/VR), industrial control, automated transportation and robotics. 5G is envisaged to support mission-critical Internet-of-Things (IoT) applications and ultra-reliable low-latency communication (URLLC) scenarios with strict requirements in terms of latency (ranging from 1 ms and below to few milliseconds) and reliability (higher than 99.999%). This entails a fundamental paradigm shift from throughput-oriented system design towards an holistic design for guaranteed and reliable end-to-end latency.

Guaranteeing URLLC requirements is a challenging task even in simple settings as URLLC drives the system to new, unexplored operating regimes. The performance is constrained by challenging fundamental tradeoffs between delay, throughput, energy and error probability. The predominance of short messages, together with the need to reduce the packet duration, implies that small blocklength channel codes are also used. This results in a rate penalty term and transmission rates with non-zero error probability, revisiting key insights obtained via asymptotic information theoretic results. Recent progress has quantified the effect of finite blocklength, providing tight bounds and accurate normal approximation for the maximum coding rate to sustain the desired packet error probability (PEP) for a given packet size [1].

In order to compensate for the reliability loss introduced by short packets, highly reliable communications mechanisms creating diversity have to be carried out, such as hybrid automatic repeat request (HARQ). However the benefits of time diversity could be rather limited under stringent latency constraints. Moreover, the benefit of feedback-based retransmissions (even with error-free but delayed feedback) is questionable since each transmit packet is much smaller due to energy and latency constraints, thus more prone to errors. Additionally, energy considerations, in particular power consumption, are of cardinal importance in the design of URLLC systems, and there is an inherent power-latency trade-off. A transmission can be successful (or its PEP may be kept unaltered) with minimum delay at the expense of additional or high power usage. In the short-packet regime, this interplay is more pronounced as latency is minimized when all packets are jointly encoded, whereas power is minimized when each packet is encoded separately. Note that power is the energy consumed over symbol period.

In this paper, we analyze the fundamental tradeoff between latency (in terms of feedback/retransmission delay) and average consumed energy in URLLC with incremental redundancy (IR)-HARQ. Considering that short packets have to be decoded with a certain PEP and latency, we give an answer whether it is beneficial to do one-shot transmission or split the packet into sub-codewords and use IR-HARQ. Prior work has considered the problem of throughput maximization by either adjusting the blocklength of each IR-HARQ round using the same power [2] or via rate refinement over retransmissions of equal-sized and constant energy packets [3]. Equal-sized and constant energy packets and rate maximization under a reliability constraint is considered in [4]. In [5], sphere packing is used for optimizing the blocklength of every transmission with equal power. In contrast to prior work, here we study the problem of average energy consumed minimization to guarantee both PEP and latency (URLLC) constraints by properly adapting both the blocklength and the power of each transmission. A key result of our paper is that one-shot transmission (no HARQ) should be used when the feedback delay is more than half the latency constraint for low and moderate blocklength.

II. SYSTEM MODEL

We consider a point-to-point communication link, where the transmitter has to send $B$ information bits within a certain predefined latency, which can be expressed by a certain predefined maximum number of channel uses, denoted by $N_r$. 
If no ARQ/HARQ mechanism is utilized, the packet of \( B \) bits is transmitted only once (one-shot transmission) and its maximum length is \( N_e \). When a retransmission strategy is employed, we consider hereafter IR-HARQ with \( M \) transmission rounds, i.e., \( M-1 \) retransmissions. Setting \( M = 1 \), we recover the no-HARQ case as a special case of the retransmission scheme. We denote \( n_m \) with \( m \in \{1,2,...,M\} \) the number of channel uses for the \( m \)-th transmission.

The IR-HARQ mechanism operates as follows: \( B \) information bits are encoded into a parent codeword of length \( \sum_{m=1}^{M} n_m \) symbols. Then, the parent codeword is split into \( M \) fragments of codeword (sub-codewords), each of length \( n_m \). The receiver requests transmission of the \( m \)-th sub-codeword only if it is unable to correctly decode the message using the previous \((m-1)\) fragments of the codeword. In that case, the receiver concatenates the first \( m \) fragments and attempts to jointly decode it. We assume that the receiver knows perfectly whether or not the message is correctly decoded (through CRC) and ACK/NACK is received error free. Every channel use (equivalently the symbol) requires a certain amount of time, therefore we measure time by the number of symbols contained in a time interval. The latency constraint is accounted for by translating it into a number of channel uses as follows: we have \( \sum_{m=1}^{M} n_m \leq N_\ell \). Penalty terms \( D(\vec{n}_m) \), where \( \vec{n}_m \) is the tuple \((n_1,n_2,...,n_m) \in \mathbb{N}_m^m \) can easily be introduced at each \( m \)-th transmission in order to take into account the delay for the receiver to process/decode the \( m \)-th packet and send back acknowledgment (ACK/NACK). In this paper, we will focus on the simplified version where \( D(\vec{n}_m) = 0 \).

The channel is considered to be static within the whole HARQ mechanism, i.e., there is only one channel coefficient value for all the retransmissions associated with the same bits. This is a relevant model for short-length packet communication and IoT applications. Indeed, for a system operating at carrier frequency \( f_c = 2.5 \) GHz, for a channel coherence time \( T_c = 1 \) ms (so equal to the URLLC latency constraint, i.e., the maximum duration of all the retransmissions associated with the same bits), the maximal receiver speed to satisfy the static assumption is \( v = cB_d/f_c \approx 180 \) km/h, where \( B_d = 0.423/T_c \) [6, (8.20)] is the Doppler spread and \( c \) is the speed of light. So for any device whose speed is smaller than 180 km/h, the channel is static during the HARQ process. This is a relatively high speed for most mission-critical IoT or tactile Internet applications. Therefore, our communication scenario consists of a point-to-point link with additive white Gaussian noise (AWGN). Specifically, in \( m \)-th round, the fragment (sub-codeword) \( c_m \in \mathbb{C}^{n_m} \) is received with power \( P_m = ||c_m||^2/n_m \) and distorted by an additive white circularly-symmetric complex Gaussian random process with zero mean and unit variance. The power allocation applied during the first \( m \) rounds is denoted by \( \vec{P}_m = (P_1,...P_m) \in \mathbb{R}_+^m \).

### III. Problem Statement and Preliminaries

The objective of this paper is to find out the HARQ mechanism maximizing the throughput by tuning the number of transmitted information bits \( B \), the number of rounds \( M \), and the blocklength-power allocation, i.e., \( (\vec{n}_m,\vec{P}_m) \), given a maximum packet error probability \( \varepsilon_{rel} \), a latency constraint \( N_\ell \) (due to URLLC requirements) and an energy budget \( E_t \).

Before going further, we need to characterize the probability of error in the \( m \)-th round of the HARQ mechanism as a function of \( (\vec{n}_m,\vec{P}_m) \). To derive this packet error probability, we resort to the results for the non-asymptotic (finite-blocklength) regime [1] since the packets we manipulate may be short.

In IR-HARQ with \( m \) transmission, the packet error probability or equivalently the outage probability, denoted by \( \varepsilon_m \), can be expressed as \( \varepsilon_m = \mathbb{P}\left(\bigcap_{i=1}^{m} \Omega_i\right) \) where \( \Omega_i \) is the event corresponding to “the concatenation of the first \( i \) fragments of the parent codeword, with length \( \vec{n}_i \) and energy per symbol \( \vec{P}_i \), is not correctly decoded when optimal coding is employed”.

When an infinite blocklength is assumed, an error occurs if the mutual information is below a threshold and for IR-HARQ, it can easily be seen that for \( i < j \) we have \( \Omega_i \subseteq \Omega_j \) [7], [8], which leads to \( \varepsilon_m = \mathbb{P}(\Omega_m) \). In contrast, when a finite blocklength (or a real coding scheme) is assumed, the above statement does not hold anymore and an exact expression for \( \varepsilon_m \) seems intractable. Therefore, in the majority of prior work on HARQ (see [2], [8], [9] and references therein), the exact outage probability \( \varepsilon_m \) is replaced with the simplified \( \varepsilon_m \) defined as \( \varepsilon_m = \mathbb{P}(\Omega_m) \), since \( \varepsilon_m \) and \( \varepsilon_m \) are numerically close. Note that for \( m = 1 \) the definitions coincide and \( \varepsilon_1 = \varepsilon_1 = \mathbb{P}(\Omega_1) \). In the remainder of the paper, we assume that this approximation is valid. Then, \( \varepsilon_m \) can be upper bounded [1, Lemma 14 and Theorem 29] and also lower bounded as in [9] by employing the \( \kappa \beta \)-bounds proposed in [1]. Both bounds have the same first two dominant terms and the error probability is approximately given by

\[
\varepsilon_m \approx Q\left(\frac{\sum_{i=1}^{m} n_i \ln(1 + P_i) - B \ln 2}{\sum_{i=1}^{m} n_i P_i (P_i + 2) / (P_i + 1)^2}\right)
\]

where \( Q(x) \) is the complementary Gaussian cumulative distribution function. For the sake of clarity, we may show the dependency on the variables, i.e., \( \varepsilon_m(\vec{n}_m,\vec{P}_m) \) instead of \( \varepsilon_m \), whenever needed.

Notice that some works have tried to approximate more accurately the term \( \varepsilon_m \) of \( \varepsilon_m \) [10]–[13]. For instance, in [10], the authors provide more involved expressions for \( \varepsilon_m \), but the feedback scheme considered is different from ours; the feedback time index in [10] is not predefined (it is a random variable) and is adapted online. In [11], [12] justifications for the approximation \( \varepsilon_m \approx \varepsilon_m \) when using non-binary LDPC codes or tail-biting convolutional code can be found. In [13], the authors used saddlepoint approximation to find a tight approximation of \( \varepsilon_m \) but provide closed-form expression only
for binary erasure channels (BEC). Therefore, we consider that using the Gaussian approximation expressed by (1) provides a relevant tradeoff between analytical tractability and tightness of the approximations.

IV. PROBLEM STATEMENT AND ITS SOLUTION

We remind we carry out an IR-HARQ to send $B$ information bits and our goal is to allocate the blocklength and power of the packet sent in every round in order to maximize the throughput. The throughput is defined as the average ratio of the successfully decoded bits divided by the number of sent symbols. The throughput can be derived thanks to the renewal theory where the expected delay is $\sum_{m=1}^{M} n_m \varepsilon m - 1$ and the expected reward is $B(1 - \varepsilon M)$. Consequently, our goal can be translated into the following optimization problems.

Problem 1: General problem

\[
\text{max}_{B,M,\varepsilon M, \tilde{P}_M} \frac{B(1 - \varepsilon M)}{\sum_{m=1}^{M} n_m \varepsilon m - 1} \tag{2}
\]

s.t. $\sum_{m=1}^{M} n_m \leq N_\ell$ \hspace{1cm} \tag{3} \\
$\varepsilon M \leq \varepsilon_{rel}$ \hspace{1cm} \tag{4} \\
$\sum_{m=1}^{M} n_m P_m \varepsilon m - 1 \leq E_\ell$ \hspace{1cm} \tag{5} \\
$M \leq M_r$ \hspace{1cm} \tag{6}

Solving the general problem is intractable. Therefore we consider a simpler one by modifying slightly the objective function. To that end, we force the numerator to be equal to $B(1 - \varepsilon_{rel})$ which means we force the constraint given by (4) to be active. This leads to the following optimization problem

Problem 2:

\[
\text{max}_{B,M,\varepsilon M, \tilde{P}_M} \frac{B(1 - \varepsilon_{rel})}{\sum_{m=1}^{M} n_m \varepsilon m - 1} \tag{7}
\]

s.t. $\sum_{m=1}^{M} n_m \leq N_\ell$ \hspace{1cm} \tag{8} \\
$\varepsilon M \leq \varepsilon_{rel}$ \hspace{1cm} \tag{9} \\
$\sum_{m=1}^{M} n_m P_m \varepsilon m - 1 \leq E_\ell$ \hspace{1cm} \tag{10} \\
$M \leq M_r$ \hspace{1cm} \tag{11}

In Lemma 1 it is proven that the solution of Problem 2 achieves almost the same performance as those of the original Problem 1.

Lemma 1: Let $(B^{mod}, M^{mod}, \varepsilon M^{mod}, \tilde{P}_M^{mod})$ be the solution of Problem 2. It gives the value $Th^*$ for the throughput according to (2). Let $Th^*$ be the highest value of the throughput given by the solution of Problem 1. Then $(B^{mod}, M^{mod}, \varepsilon M^{mod}, \tilde{P}_M^{mod})$ is a feasible point of Problem 1 and it holds that $Th \leq Th^* \leq \frac{Th}{1 - \varepsilon_{rel}}$.

Proof: The constraints of the two problems are the same, therefore they share the same feasible domain which we denote $\mathbb{D}$. So, $(B^{mod}, M^{mod}, \varepsilon M^{mod}, \tilde{P}_M^{mod})$ is a feasible point of Problem 1. Since $Th^*$ is the optimal value and $Th$ just a feasible one, $Th \leq Th^*$. Furthermore, the solution of Problem 2 guarantees that for every point in $\mathbb{D}$ it holds $\sum_{m=1}^{M} n_m \varepsilon m - 1 \leq \frac{Th}{1 - \varepsilon_{rel}}$. Therefore if $x^* \in \mathbb{D}$ is the optimal point of Problem 1 and gives an error probability of $\varepsilon M$ then $\frac{Th^*}{1 - \varepsilon_{rel}} \leq \frac{Th}{1 - \varepsilon_{rel}}$ from which we can easily derive $Th^* \leq \frac{Th}{1 - \varepsilon_{rel}}$. \hfill \blacksquare

We propose to do the optimization over $B$ via a 1-D grid-search. Consequently, Problem 2 can be still simplified and leads to the following Problem 3.

Problem 3:

\[
\min_{M,\varepsilon M, \tilde{P}_M} \sum_{m=1}^{M} n_m \varepsilon m - 1 \tag{12}
\]

s.t. $\sum_{m=1}^{M} n_m \leq N_\ell$ \hspace{1cm} \tag{13} \\
$\varepsilon M \leq \varepsilon_{rel}$ \hspace{1cm} \tag{14} \\
$\sum_{m=1}^{M} n_m P_m \varepsilon m - 1 \leq E_\ell$ \hspace{1cm} \tag{15} \\
$M \leq M_r$ \hspace{1cm} \tag{16}

The rest of this Section is devoted to the resolution of this Problem 3. We will see that it can be solved iteratively through a dynamic programming approach.

First of all, we introduce the states at the end of $m$-th round:

$S_1 = (N_1, \varepsilon_1) \hspace{1cm} \tag{17}$

$S_m = (N_m, \varepsilon_m, E_m, V_m), m \in \{2, 3, \ldots\}$

where $\forall m \in \mathbb{N}^*: N_m = \sum_{i=1}^{m} n_i$, $E_m = \sum_{i=1}^{m} n_i P_i \varepsilon_{i-1}$ and $V_m = \sum_{i=1}^{m} n_i (1 - \frac{1}{1 + P_i})$. We have $V_m < N_m \leq N_r$. Let $S_M$ be the set of feasible final states. By feasibility, we mean that a state $S_M$ in $S_M$ satisfies the constraints in Problem 3. We have $S_M \subset \{1, 2, \ldots, N_\ell \} \times [0, \varepsilon_{rel}] \times [0, E_\ell] \times [0, N_r] \hspace{1cm} \forall M \in \{1, 2, \ldots, M_r\}$. Our objective is to find the optimal sequence/path of states minimizing (12) which will provide the optimal vector $(\tilde{n}_M, \tilde{P}_M)$ solving Problem 3. Indeed, each solution (and so the optimal one) represented by a path $(\tilde{n}_M, \tilde{P}_M)$ leads to an $S_M \in S_M^*$.

The first three variables of the states $S_m$ were chosen in order to be able to check the constraints (13-15). The dispersion variable $V_m$ was added such that the sequence of $S_m$ is a Markov chain since the description of $S_m$ then depends only on the previous state $S_{m-1}$ and the variables $n_m$ and $P_m$ which constitute the branch between $S_{m-1}$ and $S_m$. The functions connecting these states can be easily found and let them be: $S_m = f_S(S_{m-1}, n_m, P_m)$, $S_{m-1} = f_S^{-1}(S_m, n_m, P_m)$.

For sake of simplicity, we introduce the following notation “$\min f(X)$” which stands for “minimize $f(\cdot)$ over the vari-
ables $X$ given constraints $Y^\prime$. Now the Problem 3 can be seen as the solution of:

$$\min_{M,S_M \in S_M|M \in \{1,..,M\}} \left\{ \min_{\vec{n}_M, \vec{P}_M | S_M} \sum_{m=1}^{M} n_m \varepsilon_{m-1} \right\}$$

over the constraints (13)-(15).

As roughly-mentioned previously, we perform the outer minimization by exhaustive search (even though, we will prove below that only a few states $S \in S_M$ are good candidates). On the other hand, the inner minimization is solved dynamically since it can be written as:

$$\min_{n_M, P_M|S_M} \left\{ \min_{\vec{n}_{M-1}, \vec{P}_{M-1}|S_{M-1}, n_M, P_M} \left\{ n_M \varepsilon_{M-1} + \sum_{m=1}^{M-1} n_m \varepsilon_{m-1} \right\} \right\}$$

The inner minimization is done under fixed $(S_M, n_M, P_M)$ which allows the first term $n_M \varepsilon_{M-1}$ to get out as a constant since this term can be expressed as a function of only those fixed variables. Moreover, $S_{M-1} = f_{S-1}(S_M, n_M, P_M)$ is fixed which can be confirmed that it is an equivalent to $(S_M, n_M, P_M)$ constraint when minimizing the second term. So, we have

$$\min_{\vec{n}_{M-1}, \vec{P}_{M-1}|S_{M-1}} \left\{ \sum_{m=1}^{M-1} n_m \varepsilon_{m-1} \right\} = \min_{n_M, P_M|S_M} \left\{ K(S_M, n_M, P_M) + \min_{\vec{n}_{M-1}, \vec{P}_{M-1}|S_{M-1}=f_{S-1}(n_M, P_M, S_M)} \left\{ \sum_{m=1}^{M-1} n_m \varepsilon_{m-1} \right\} \right\}$$

The above formula can be proven for every $m \in \{1,..,M\}$ which allows to apply the dynamic programming approach. Specifically to find the optimal solution for the state $S_m$ it is sufficient to know the optimal solution of every $S_{m-1}$ connected to it through a branch $(n_m, P_m)$. Therefore we can start by straightforwardly computing the values for each feasible $S_1$ and afterwards in every $m$ iteration of the dynamic programming algorithm we compute the optimal solution for $S_m$ by using the corresponding $S_{m-1}$.

Finally, the optimal solution of Problem 3 has some characteristics which reduce the number of states to test.

**Lemma 2:** When $M$ grows, feasible points of Problem 3 with better values of the objective function (12) appear. Therefore the optimal solution satisfies (16) with equality, i.e. $M^* = M_r$.

**Proof:** In [14, Appendix C], it is proven that if the last, i.e. $M$-th, packet with $(n_M, P_M)$ blocklength and power is properly split into two packets with $(n'_M, P_M)$ and $(n_{M-1} = n_m - n'_M, P_M)$ then the average energy is decreased. The same splitting straightforwardly can be shown to decrease our objective (12) and therefore this new configuration with an extra round gives better result while satisfying the constraints. Therefore more rounds lead to better performance. ■

**Lemma 3:** Let $(M^*, \vec{n}_{M^*}, \vec{P}_{M^*})$ be the optimal point of Problem 3. We remind that $M^* = M_r$, due to Lemma 2. Let $\varepsilon_m^* = \varepsilon(m, \vec{n}_m^*, \vec{P}_m^*)$ where $\vec{n}_m$ (resp. $\vec{P}_m$) is an extracting vector from the $m$-th first components of $\vec{n}_M^*$ (resp. $\vec{P}_M^*$), be the error probability at every round $m < M_r$. We have $\varepsilon_m^* > \varepsilon_{rel}$ and finally at round $M_r$ we have $\varepsilon_m^* \leq \varepsilon_{rel} < \varepsilon(\vec{n}_{M-1}^*, \vec{n}_{M-1}^* - 1, \vec{P}_{M-1}^*)$.

**Proof:** Assume that for $m_0 < M_r$ we have $\varepsilon_{m_0}^* < \varepsilon_{rel}$. Then the point $(m_0, \vec{n}_{m_0}^*, \vec{P}_{m_0}^*)$ is a better than the optimal point which leads to contradiction. Furthermore, to prove $\varepsilon_M^* \leq \varepsilon_{rel} < \varepsilon(\vec{n}_{M-1}^*, \vec{n}_{M-1}^* - 1, \vec{P}_{M-1}^*)$ is fairly simple since the first inequality is the reliability constraint and the second cannot be violated since otherwise the point $(\vec{n}_{M-1}^*, \vec{n}_{M-1}^* - 1, \vec{P}_{M-1}^*)$ is a better than the optimal solution which again leads to a contradiction. ■

As $\varepsilon^*_m \leq \varepsilon_{rel} < \varepsilon(\vec{n}_{M-1}^*, \vec{n}_{M-1}^* - 1, \vec{P}_{M-1}^*)$, we can conjecture that $\varepsilon^*_M \approx \varepsilon_{rel}$ since the last round will enable to satisfy the constraints but not going to far away from it because it will be costly in throughput (if $n_M$ is selected too high) or in energy (if $P_M$ is selected too high). Therefore we will also that $E^*_M \approx E_r$ where $E^*_M$ is the energy consumed by the optimal solution of Problem 3.

V. IMPLEMENTATION

The dynamic programming algorithm needs in practice the variables of the states to take discrete values. Specifically:

- $N_m$ has already a discrete form since it is an integer inside the interval $[0, N]$ but for accelerating the simulation it can be also quantized using bigger than one symbol step size. Let $\mathbb{N}$ be the set of the discrete values that $N_m$ can take.

- $\varepsilon_m$ is real and from lemma 3 we know $\varepsilon_m \in [0, \varepsilon_{rel}]$. It turns out that if instead of $\varepsilon_m$ the use of the equivalent (due to $Q^{-1}(\cdot)$ being a one-to-one mapping) variable $c_m := Q^{-1}(\varepsilon_m)$ is employed, more accurate results are yielded. If we assume only realistic error probabilities of value lower than 0.5 then $c_m \in [0, Q^{-1}(\varepsilon_{rel})]$. Let $\mathbb{C} \subset [0, Q^{-1}(\varepsilon_{rel})]$ be the set of the discrete values that the dynamic algorithm allows $c_m$ to take.

- $E_m$ is real and $E_m \in [0, E_r]$. After quantization let $E$ be the set of the discrete values $E_m$ can take.

- $V_m$ is real and $V_m \in (0, N_m) \subset (0, N)$. After quantization let $V$ be the set of the discrete values $V_m$ can take.

The dynamic algorithm consists of two stages: the first one to compute for the feasible states their performance and the second one to search over those states to find the optimal solution. The complexity is governed by the first stage and is equal to the number of iterations the dynamic algorithm takes, multiplied by the number of states examined per iteration, multiplied by the number of branches departing from every state. In our implementation, we compute the branch $(n_{m+1}, P_{m+1})$ departing from a state $S_m$ through fixing the variables $N_{m+1}$ and $E_{m+1}$ of the arriving state $S_{m+1}$ and subsequently we acquire the feasible $\varepsilon_{m+1}$ and $V_{m+1}$. Therefore the overall complexity is $O(M_r \cdot |\mathbb{N}| \cdot |\mathbb{E}| \cdot |\mathbb{C}| \cdot |\mathbb{V}| \cdot |\mathbb{E}|)$. The above complexity displays a slow algorithm but in reality it can be faster by remarking that most of the times all of the paths ending up at states with the same $(N_m, c_m, E_m)$ which the algorithm considers, present dispersions $V_m$ within
a small range of values. Therefore if a reasonable resolution of the discrete set $V$ is considered so as no significant approximation errors to be introduced, then the number of feasible states with same $(N_m, e_m, E_m)$ and different $V_m$ turns out to be rather small (many times just one value). Therefore the variable $|V|$ can be thought as constant which in our simulations never exceeds 10.

VI. NUMERICAL RESULTS AND DISCUSSION

In this section, we provide numerical results to illustrate the behavior of the system. First we inspect how the error probability affects the throughput. Specifically we solve Problem 2 with reliability constraint (9) to be equality and we let the achieved $e_{rel}$ to take different values. This procedure actually requires only one run of the dynamic algorithm because after the computation of the performance of each state we can restrict the research of the minimum only between the states with the given $e_m$. In that way Fig. 1 is obtained.

Now we analyze the influence of the number of used symbols on the throughput. In order to obtain Fig. 2, we force equality in the latency constraint (8) of Problem 2, and the error probability is treated as for Fig. 1.

![Fig. 2. Throughput Versus Used number of symbols when $e_{rel} = 10^{-5}, B = 32$Bytes, $M_r = 3$](image)

When the available number of symbols are inadequate (too weak), no feasible solution appears and the throughput vanishes. Interestingly as $N_{M_r}$ grows beyond a certain threshold, only a slight increase of the throughput is obtained, followed by a slow decrease. This means that it is not always beneficial for throughput to use the whole available blocklength. Asymptotically if $N_{M_r} \to \infty$ then for some $m \in \{1, \cdots, M_r\}$ it should $n_m \to \infty$ which will result to vanishing the throughput.

For Fig. 3, we plot the throughput versus the energy budget. In practice, we do not force equality in the energy constraint (10), since as stated previously the optimal solution consumes by default (almost) all the available energy. In our simulations, we set the minimum possible blocklength for the first HARQ round to be $N_{1, \text{min}} \geq 100$ (which was set likewise so as Polyanskiy’s formula (1) to remain accurate). Consequently the throughput cannot exceed the value $\frac{B}{N_{1, \text{min}}}$, which represent the fictional case of only one packet sent with minimum blocklength and achieving perfect reliability. This lower bound is closely approached as the available energy grows to finally be enough so that only one transmission fulfills the constraints. Further increase of the energy is wasteful. Finally, Fig. 3 confirms again (as in Fig. 2) that when we are beyond a certain threshold, any additionally increase of the available blocklength is useless.

For Fig. 4, we depict the throughput (via a contour plot) versus the available average energy $E_t$ and the information bits to transmit $B$. There is an upper left area where there are no feasible points. Keeping a constant $E_t$ by moving vertically on Fig. 4, we see that the throughput is a unimodal function over $B$ and there is a specific value of $B$ achieving optimality.

![Fig. 1. Throughput Versus Attained Error Probability when $N = 400, E_f = 267, B = 32$Bytes](image)
This also agrees with [3] when a simple ARQ scheme with no URLLC constraints was employed.

VII. CONCLUSION
